Abstract

Alzheimer’s disease (AD) is a progressive neurodegenerative disorder characterized by globally impaired cognitive functions. Oxidative stress is involved in the formation of plaques and tangles, which damage neuronal cells in AD. Treatments retarding the progression of AD or significantly improving cognition are not available. Diet has been recognized as a modifiable lifestyle factor capable of affecting the risk of developing AD, since it may influence inflammation and oxidative stress in the brain. Dietary intake of natural antioxidants, such as polyphenols, carotenoids and vitamins C and E, is thought to reduce oxidative stress and to have preventive or therapeutic potential in AD. Several antioxidants have shown promise in animal models of AD. However, there is no evidence of clinical efficacy of natural antioxidants in people with AD. The use of antioxidants may be hindered by their limited bioavailability. Furthermore, antioxidants administered in high concentrations could have detrimental effects due to their capacity to act as prooxidants. Potential effects of natural antioxidants in the prevention of AD should be assessed in studies with long-term exposure to compounds with high bioavailability. In addition, the assessment of the effectiveness of antioxidant-rich diets in AD deserves further investigation.

Keywords: Alzheimer’s disease; Antioxidants; Oxidative stress; Prevention; Prooxidant activity.

1. Introduction

Alzheimer’s disease (AD) is a progressive neurodegenerative disorder characterized by globally impaired cognitive functions, including memory, language, executive and other behavioral functions, and a marked decline in activities of daily life (Lange et al. 1995; Scheltens et al. 2016). AD is the most common form of dementia, occurring in approximately two thirds of affected individuals (Scheltens et al., 2016). The disease is characterized by neuronal and synaptic loss, and its neuropathological hallmarks are the extracellular deposition of misfolded amyloid-β (Aβ) in senile plaques and the intracellular accumulation of hyperphosphorylated tau forms in neurofibrillary tangles (Butterfield and Lauterbach, 2002; Crews and Masliah, 2010). The pathogenesis of AD is complex and incompletely understood. The accumulation of the neurotoxic Aβ peptide in the brain appears to play a critical role in the pathophysiology of AD, causing oxidative stress and neuroinflammation and ultimately leading to neuronal dysfunction and cell death (Butterfield and Lauterbach 2002; Querfurth and LaFerla 2010). Disease-modifying therapies retarding the progression of AD or significantly improving cognitive functions in those affected by AD are currently not available (Scheltens et al. 2016).

AD has long been believed to be an inevitable consequence of aging. However, modifiable lifestyle behaviors are gaining increasing recognition as factors capable of affecting the risk of developing AD (Lange, 2018a; Sohn, 2018). In particular, diet and nutrition may play a role, since they can modulate brain structure and connectivity and affect cerebral and behavioral changes associated with aging and disease (Gustafson et al. 2015; Huhn et al. 2015). Nutritional approaches to AD include ketogenic diets targeting energetic deficits and reduced glucose utilization in AD (Lange et al., 2017), dietary patterns, such as the Mediterranean diet, with components that may beneficially affect pathophys-
The characteristic brain lesions in AD (Harman, 2006; Pimplikar et al., 2006) are early features of AD and a major contributor to the development of Alzheimer’s disease (Lange et al., 2019a; Lange et al., 2019b; Lange et al., 2019c).

2. Oxidative stress in AD

Reactive oxygen species (ROS), such as superoxide anion, hydroxyl radical, singlet oxygen, nitric oxide, alkoxyl and peroxyl radicals, are produced as a normal part of metabolism within the mitochondria (Sies, 1985). External factors promoting the production of free radicals include, for example, environmental pollutants, smoking, radiation and drugs. The endogenous antioxidant capacity is a multi-component system capable of neutralizing ROS to prevent damage of cellular compartments. A balance between the generation of ROS and the antioxidative defense system exists. In particular, the oxidation of unsaturated lipids in body tissues can be prevented effectively under normal conditions. Various enzymes, such as glutathione peroxidase and superoxide dismutase, are involved in the in vivo redox homeostasis and maintain intracellular ROS at low levels (Sies, 1985).

Oxidative stress in biological systems is characterized by an imbalance between the production of ROS and their removal by the antioxidant system (Harman, 1981; Sies, 1985), with an associated disruption of redox circuits and macromolecular damage (Jones, 2006). The concentrations of ROS can exceed the removal capacity of the antioxidant system due to metabolic demand during aging or under pathological conditions. Excessive production and uncontrolled regulation of ROS can cause biological dysfunction (Yu, 1994; Dröge, 2002).

The brain is particularly prone to oxidative stress-induced damage due to its low antioxidant response capacity; it consumes around 20% of total body oxygen and contains high concentrations of polyunsaturated fatty acids subject to lipid peroxidation under conditions of high metabolic activity and oxygen utilization (Behl et al., 1994; Romero et al., 1998). The initiation of lipid peroxidation makes the brain a major target for neurodegeneration. ROS have been shown to act as secondary messengers in various intracellular signaling pathways and as mediators of inflammation and oxidative damage (Waldbaum and Patel, 2010). Furthermore, oxidative stress appears to be self-propagating, since cellular macromolecules, damaged by oxidative stress-induced excessive release of ROS, may convert themselves into ROS (Hulbert et al., 2007).

Accumulating evidence suggests that ROS generated via a variety of mechanisms may play complex pathogenetic roles in AD (Liu et al., 2018). The development of AD is associated with oxidative damage in the brain, including oxidation of nucleic acids, lipids, proteins and carbohydrates (Nunomura et al., 2006). Progressively increasing oxidative stress has been suggested to be an early feature of AD and a major contributor to the development of the characteristic brain lesions in AD (Harman, 2006; Pimplikar et al., 2010). Oxidative stress may be a result of mitochondrial failure and/or compromised antioxidant capacity with reduced concentrations of endogenous antioxidants. Oxidative events appear to occur before the onset of Aβ accumulation and plaque formation, which lends support to the critical role of oxidative stress in the early stages of AD (Lin and Beal, 2006; Wang et al., 2014). For example, the modulation of JNK/p38 MAPK pathways by oxidative stress leads to Aβ accumulation and tau protein hyperphosphorylation (Patten et al., 2010). The targeting of DNA by ROS is a particular problem in aged brains, since they have been shown to exhibit elevated levels of mitochondrial DNA mutations induced by oxidative stress (Chomyn and Attardi, 2003; Kraysberg et al., 2003; Trifunovic et al. 2004). While oxidative stress appears to be an important factor contributing to the initiation and progression of AD, the exact mechanisms involved in the disruption of redox balance and the sources of ROS remain unknown.

Since antioxidants can scavenge reactive radicals and prevent oxidation of substrates at low concentrations (Halliwell and Gutteridge, 1995), they are able to sustain cell integrity and are therefore vital to the defense system of plants, animals and humans. Furthermore, the findings of animal studies suggest that antioxidants may have anti-amyloidogenic effects (Ono et al., 2006). Therefore, the regulation of ROS levels using antioxidants may provide a potential therapeutic approach capable of impeding neurodegeneration in AD.

3. Natural antioxidants

Antioxidants have been defined as substances that delay, prevent or remove oxidative damage to a target molecule (Halliwell, 2007). The endogenous antioxidant system in humans, consisting of enzymatic and non-enzymatic antioxidants, is not sufficient to maintain the concentrations of free radicals at low levels and depends on the exogenous supply of various antioxidants through the diet (Piatta, 2000). Most exogenous natural antioxidants are phytochemicals. Major natural antioxidants with potential therapeutic benefits in AD, including vitamins C and E, carotenoids and flavonoids, may be found in certain foods. Diets rich in fruits and vegetables appear to have protective effects against various diseases and have been reported to be associated with reduced rates of cardiovascular disease and cancer (Cox et al., 2000; Gillman et al., 1995; Joshipura et al., 1999; Strandhagen et al., 2000). Antioxidants are believed to be the primary food bioactives providing the protection afforded by fruits and vegetables (Eastwood, 1999). A review of epidemiological studies concluded that the high content of polyphenolic antioxidants in fruit and vegetables is likely to be the main factor responsible for the health benefits observed (Potter, 1997).

Since antioxidant compounds play an important role in scavenging free radicals, their use has been increasingly promoted as a potential strategy in preventing or reducing neuronal cell death. Exogenous antioxidants have been found to decrease the toxicity of β-amyloid in the brains of people with AD (Behl, 1997; Christen, 2000). However, little information is available on the efficacy of natural antioxidants in neurodegenerative diseases (Pohl and Kong Thoo Lin, 2018).

In regard to halting neurodegeneration, a variety of natural oxidants have shown promising results in animal models and cell culture studies. For example, dietary polyphenols, including resveratrol, curcumin, catechins and anthocyanins, have been demonstrated to obstruct the initiation and progression of Alzheimer’s disease in animals by inhibiting oxidative stress, DNA damage, β-amyloid aggregation and cell apoptosis in neurocytes (Bastianetto et al., 2007; Darvesh et al., 2010; Mercer et al., 2005). In transgenic mice with an overexpression of Aβ, the administration of the polyphenol epigallocatechin-3-gallate from green tea has been found to significantly decrease Aβ deposition, to modulate tau pathology and to reduce β-amyloid-mediated cognitive impairment (Rezai-Zadeh et al., 2005; Rezai-Zadeh et al., 2008). Furthermore, the administration of ferulic acid protects mice against Aβ peptide toxicity induced by intracerebral injection of β-amyloid peptide (Yan et al., 2001). Both ferulic acid (Mori et al., 2013) and tannic acid (Mori et al., 2012) markedly decreased AD-like pathology in rats through the inhibition of β-secretase.
Furthermore, reduced serum antioxidant levels in humans associated with an increased AD risk may indicate a therapeutic value of their use. For example, a survey conducted in almost 7,000 adults aged 50 years and over found a significantly negative association between the serum concentrations of lycopene and lutein and the risk of AD, which suggests that increased consumption of foods rich in these compounds could decrease the risk (Min and Min, 2014).

Flavonoids and related polyphenols from grapes and other fruits have shown free radical scavenging activity and antioxidant and anti-inflammatory effects (Joseph et al., 2005). Flavonoids such as quercetin, anthocyanidins and catechins are all antioxidants that may have preventive effects on the aging of brain functions (Alaei et al., 2015). The best-studied fruit polyphenol, the stilbenoid resveratrol (trans-3,5,4′-trihydroxystilbene), has antioxidant and anti-inflammatory properties. The findings of in vitro and in vivo studies suggest that resveratrol could have potential in the treatment of AD (Lange, 2018b; Lange and Li, 2018). In addition to its antioxidant activities, resveratrol is also capable of modulating signaling pathways and activating longevity genes such as sirtuins (Calabrese et al., 2008; Crichton et al., 2013; Lange and Li, 2018; Witte et al., 2014). Resveratrol has also been shown in humans to have beneficial effects on glucose control (Bhatt et al., 2002; Brasnyó et al., 2011; Crandall et al., 2012) and blood flow (Kennedy et al., 2010).

Despite a multitude of potential neuroprotective mechanisms related to resveratrol, the translation of the findings in animals to humans to have beneficial effects on glucose control (Bhatt et al., 2002; Brasnyó et al., 2011; Crandall et al., 2012) and blood flow (Kennedy et al., 2010).

4. Natural antioxidants contained in diets

The failure of specific antioxidants to prevent AD in intervention studies has led some researchers to adopt a more holistic view of food intake. Emerging evidence suggests that combinations of appropriate antioxidants may have synergistic effects and may be more effective than single compounds (Veurink et al., 2020). A combination of antioxidants has been shown to be effective in decreasing apoptosis and markedly improving learning and memory in transgenic mice (Veurink et al., 2003).

A population-based, prospective cohort study conducted in the Netherlands, comprising 5,395 participants aged >55 years with a reliable dietary assessment using a food-frequency questionnaire, showed that a high dietary intake of vitamin C and vitamin E was associated with a reduced risk of AD after a mean follow-up of 6 years; adjustments for a large number of potentially confounding variables were made (Engelhart et al., 2002). It should be noted that consumption of antioxidants contained in food reflects long-term intake. In comparison with supplementation of synthetic compounds, antioxidants from food are consumed simultaneously with other nutrients in a balance that may affect absorption or biological activity (Bronner, 1993).

Prospective studies have reported that high levels of dietary flavonoid intake were associated with a lower risk of AD (Commenges et al., 2000; Engelhart et al., 2002). In a recent prospective, community-based cohort study comprising 921 participants with a mean age of 81.2 years, dietary consumption of flavonols, as assessed using a validated food frequency questionnaire, was negatively associated with incident AD in models adjusted for age, sex, education, genetic predisposition and participation in cognitive and physical activities (Holland et al., 2020). These results suggest that higher dietary intake of flavonols may be associated with a decreased risk of developing AD. Well-designed trials are required to confirm the clinical relevance of these findings.

The Mediterranean diet contains high concentrations of natural antioxidants, including phenolics, carotenoids, and vitamins C and E (Scarmeas et al., 2006; Vasto et al., 2012). In epidemiological studies, individuals adhering to a Mediterranean diet were related to an elevated incidence of mild cognitive impairment and AD (Gardener et al., 2012). Strict adherence to a Mediterranean diet was associated with a reduction in AD by 34% (Gu et al., 2010). Healthy, middle-aged individuals who had followed this diet showed less brain atrophy in magnetic resonance imaging and less Aβ accumulation than those who had not, demonstrating the neuroprotective effects of the Mediterranean diet (Berti et al., 2018; Mosconi et al., 2018). However, the majority of investigations on the Mediterranean diet and AD are observational and cannot answer the question whether the association is causal. A confounding factor in these studies is, for example, the interactions between diet and other lifestyle factors, such as physical exercise (Lange, 2018a).

The wide variety of antioxidants contained in the Mediterranean diet shows promise for the prevention and treatment of AD. However, further research is required to fully understand the mechanisms by which these antioxidants exert their protective effects. Future studies should focus on identifying optimal doses and combinations of antioxidants, as well as investigating potential interactions with other lifestyle factors and medications.
nean diet may contribute to a decrease in oxidative stress and the reduced risk of dementia (Dai et al., 2008; Luchsinger et al., 2004; Morris et al., 2002; Paleologos et al., 1998). The Mediterranean diet may also increase plasma concentration of brain-derived neurotrophic factor, which protects neurons against oxidative stress (Sánchez-Villegas et al., 2011). Although the traditional Mediterranean diet is rich in natural antioxidants, other food components of the diet, such as omega-3 polyunsaturated fatty acids from fish and monounsaturated fatty acids from olive oil, may contribute to the beneficial effects in regard to AD by decreasing or preventing inflammation (Huang et al., 2013). In addition, the reduced risk of AD associated with the Mediterranean diet could be mediated through a decrease in vascular risk factors and beneficial effects on glucose and lipid metabolism (Biesels et al., 2006; Esposito et al., 2007; Hu et al., 2013; Martínez-González et al., 2008; Pangiotakos et al., 2003; Rumawas et al., 2009; Stampfer et al., 2000).

In summary, diets rich in fruits and vegetables containing cocktails of natural antioxidants are likely to be beneficial in the prevention of AD. However, our knowledge of the quality and quantity of individual food bioactives required for effective neuroprotection is insufficient.

5. Prooxidant activity of antioxidants

Even when seemingly natural and healthy food bioactives are supplemented, possible adverse effects need to be considered (Dunn et al., 2010; Klein et al., 2011; Lange et al., 2019d). For example, the administration of antioxidants in high doses has been observed to cause adverse effects (Zadák et al., 2009), possibly due to prooxidative activity. Biological systems have been postulated to require a balance between oxidation and antioxidation, with low amounts of antioxidants being favorable to this system and high doses disrupting the balance (Bouayed and Bohn, 2010).

Prooxidants are substances that induce oxidative stress through the formation of ROS or by inhibiting the antioxidant system. While natural antioxidants are used for their preventive and therapeutic effects, compounds such as polyphenols, flavonoids, carotenoids and anthocyanins, administered at higher doses or under certain conditions, may also act as prooxidants, producing free radicals, causing DNA damage and mutagenesis and aggravating states of disease (Egbaliferiz and Iranshahi, 2016). The antioxidant-induced reduction in cell damage may boost the occurrence of neoplasia, since the administration of antioxidants may facilitate the survival of genetically damaged cells (Halliwell and Gutteridge, 2015). For example, epidemiological studies have indicated that diets high in carotenoid-rich fruits and vegetables and elevated serum concentrations of β-carotene are associated with a reduced risk of lung cancer (Mayne, 1996; Peto et al., 1981; Ziegler, 1991). However, an increase in the incidence of lung cancer was observed in heavy smokers receiving β-carotene supplements for several years (Alpha-tocopherol, beta carotene cancer prevention study group, 1994; Blumberg and Block, 1994; Ommen et al., 1996). The latter finding can probably be attributed to the antioxidant effect on cell proliferation (Khlebnikov et al., 2007).

Factors that can transform the function of an antioxidant into a prooxidant include the presence of metal ions, the redox potential of the antioxidant and its concentration in matrix environments (Gonzalez et al., 2005; Ionescu et al., 1998; Ionescu et al., 2006). The potent antioxidant vitamin C can act as a prooxidant depending on the dose administered, with antioxidant and prooxidant effects following low and high doses, respectively (See and Lee, 2002). The prooxidant effect of vitamin C is also found when the vitamin is combined with iron or copper (Duarte and Lunec, 2005; Podmore et al., 1998), with the reduced transition metals reducing hydrogen peroxide to hydroxyl radicals through Fenton reaction (Asplund et al. 2002; Urbanískis and Beresewicz, 2000). Vitamin E (α-tocopherol) is also a potent antioxidant that may become a harmful prooxidant in high concentrations (Carlisle et al. 2000; Blumberg and Block, 1994). In a systematic review and meta-analysis, elevated mortality rates were found following extended supplementation with β-carotene as well as vitamins A and E (Bjelakovic et al., 2007). Flavonoids have also been shown to act as prooxidants in the presence of transition metals, which catalyze the redox cycling of polyphenols and could lead to the formation of ROS and phenoxyl radicals (Galati and O’Brien, 2004; Halliwell, 2008; Yordi et al., 2012).

Future human studies should clarify the importance of prooxidative activity of phenolics and carotenoids at the doses administered under physiological conditions, since most available findings stem from in vitro experiments using high doses of antioxidants (Wang et al., 2015). Furthermore, the prooxidant activity of polyphenols has been found in the presence of transition metals, such as iron and copper, and the concentrations of these metals in biological systems are lower than those assessed in in vitro studies (Egbaliferiz and Iranshahi, 2016). Therefore, the possible prooxidant activity of natural antioxidants consumed in foods containing a combination of them may be limited. In addition, prooxidants have been hypothesized to have essential cell signalling properties (Procházková et al., 2011) and other beneficial effects, since a mild degree of oxidative stress could lead to cytoprotection through a prooxidant-induced rise in the levels of antioxidant defenses and xenobiotic-metabolizing enzymes (Halliwell, 2008).

6. Future directions

More definitive studies are needed to examine the efficacy of natural antioxidants in AD. Various factors need to be considered in the study design of future investigations. Important aspects are the optimum age for the initiation of antioxidant consumption and the duration of intake. Since the pathogenetic process leading to dementia may begin many years prior to the onset of symptoms, supplementation may have to be initiated in young or middle age. In humans, significant effects would become observable only following decades-long consumption of antioxidants, which would render respective studies unfeasible. Since optimal results of the administration of antioxidants may be expected in early or even presymptomatic stages of AD, the diagnostic identification of subtle neuropathological alterations and biomarkers related to the disease process are required. Furthermore, the tools currently used to assess outcomes may not be able to detect minimal changes in cognitive functions in early stages of AD (Morrison et al., 2013).

The bioavailability of polyphenols is limited; they are poorly absorbed and extensively metabolized, resulting in low serum levels (Bravo, 1998; Cottart et al., 2010; Crozier et al., 2010; Del Rio et al., 2010). The concerns regarding the bioavailability of natural antioxidants stem from studies of the pharmacokinetics of certain agents such as resveratrol. However, the effects of polyphenols could be mediated through the active metabolites of these compounds or through synergistic effects of several polyphenols in juice or fruit extracts (Cottart et al., 2010; Scalbert and Williamson, 2000). Future pharmacokinetic studies need to address the question of the most effective form of antioxidant consumption,
considered as medicinal products and should therefore be evaluated extensively in the same way as new drugs prior to marketing. In addition, the assessment of the effectiveness of antioxidants to maximize bioavailability to different cellular compartments and enhance bioavailability (Gao, 2016).

Furthermore, in view of possible toxic effects of curcumin (Burgos-Moron et al., 2010), antioxidant supplements should be considered as medicinal products and should therefore be evaluated extensively in the same way as new drugs prior to marketing.

7. Conclusion

Due to its high oxygen consumption and high lipid content, the brain is highly susceptible to oxidative stress. The accumulation of ROS poses a significant threat to neurons. When production of these species exceeds the brain’s antioxidant defense capacity, substantial neuronal damage may result. It is well established that oxidative damage of neuronal molecules has a major impact on AD. The pathogenetic role of oxidative stress in AD has led to the proposal that increased consumption or supplementation of plant-derived antioxidants may reduce the development of neuronal dysfunction and may offer preventive or therapeutic potential in AD. Several antioxidants have shown promise in animal models of AD. However, the findings regarding effects of antioxidants in AD in humans are controversial and inconclusive. Single antioxidants may not suffice in preventing oxidative damage in AD, since a wide variety of endogenous and exogenous antioxidants are involved in the modulation of oxidative stress. Therefore, effects of dietary natural antioxidant cocktails require further investigation regarding the prevention of AD. Furthermore, the use of antioxidants in humans may be hindered by limited bioavailability and insufficient bioactivity in the brain. There is currently no evidence of clinical efficacy of natural antioxidants in people with AD (see Table 1).

While antioxidant scavenging of free radicals may have health benefits, it may also have detrimental effects. Antioxidants, especially when administered in high doses, could disturb the homeostasis associated with the role of ROS in various physiological processes. A controversy surrounding dietary antioxidants concerns their capacity to act as (toxic) prooxidants, depending on their concentration and the presence of other molecules. Antioxidant activity might increase the survival of precursor tumor cells in altered matrix environments and could thus enhance malignancy.

Potential effects of natural antioxidants in the prevention of AD need to be assessed in studies with long-term exposure to compounds with high bioavailability. Large-scale clinical trials employing sensitive, valid, reliable and ecologically meaningful assessments are needed to establish the therapeutic efficacy of antioxidants. Future studies should employ combinations of antioxidants to maximize bioavailability to different cellular compartments. In addition, the assessment of the effectiveness of antioxidant-rich diets in AD warrants further investigation.
